# Final Report on NASA Grant NAGW5-2168

## Studies of a Free-Flying Astromag Mission

R. A. Mewaldt and E. C. Stone

April 7, 1995

Abstract: This is the final report on work funded by NASA grant NAGW5-2168 entitled "Studies of a Free-Flying Astromag Mission". This grant was originally funded to cover the period from 1 November 1992 to 30 April 1993. Following this a no-cost extension was granted that extended to 12/31/93.

Introduction: In 1989, after extensive study (Ormes et al. 1986), the Astromag Superconducting Magnet Facility was selected for flight on the Space Station, including three experiments, Wizard, LISA, and SCIN-MAGIC. Two years later, Astromag and a number of other payloads were indefinitely suspended from consideration from flight on Freedom when the Space Station was descoped. Subsequent to this, a new study carried out by Goddard Space Flight Center (Ormes et al. 1990) determined that the vast majority of the objectives of Astromag could also be carried out by a free-flying mission launched by an Atlas-IIAS rocket. Following the NASA Woods Hole planning meeting in 1991, it was clear that overall mission costs would be a primary consideration for determining the experiments that NASA ultimately selected for spaceflight.

: : :...

It was within this climate that a small amount of money was made available to determine whether the costs of Astromag could be further reduced, without sacrificing its primary science objectives, by accomodating it on a Delta launch vehicle. The study summarized in this final report is part of that effort. The objective of this study was to determine to what extent the objectives of the LISA Experiment could be accomplished by a scaled-down instrumentation and a smaller magnet compatible with the resources available on a Delta-class mission.

The scientific objectives of the LISA experiment (see Binns et al. 1989) are to 1) extend measurements of the isotopic composition of cosmic ray elements from Be to Ni (Z = 4 to 28) into the energy

range beyond 1 GeV per nucleon; 2) to measure the energy spectra of heavy elements up to energies >100 GeV/nucleon with good statistical accuracy, and 3) to search for heavy anti-matter with Z>2 in cosmic rays. In the present study the SRL group proposed to study three topics. The results obtained in each of these areas are summarized below.

1) Adaption of the LISA Cherenkov Counters to a Smaller Size Astromag: For orientation, Figure 1 shows a cross section of the LISA experiment for the Space Station and Atlas versions of Astromag. The key subsystems are the magnet, the tracking system, the Cherenkov system, consisting of a number of modules, and the TOF system. During the course of this study GSFC considered various possible accomodations of Astromag within a Delta Launch vehicle, along with a number of possible orbits and design lifetimes. As a result, the mass and power allocated to the instruments was constantly changing, and several different versions of smaller size experiments were considered. Figures 2, 3, 4, and 5 show rough sketches of seven possible versions, all of which fit within the 2.5 m radius of a Delta shroud.

In order to provide quick feedback on the required resources for these various versions a spreadsheet was developed that included scaling laws to estimate the mass and power of not only the Cherenkov system, but also the LISA experiment as a whole, since the overall design of LISA was driven by the number of Cherenkov modules. Table 1 shows a detailed breakdown for the Cherenkov subsystem for nine possible versions. Among the weight-saving modifications that were introduced were VLSI electronic circuitry (see below), and carbon fiber structural support.

A summary of these mass and power estimates for the first seven options is included in the attached report dated 10/26/92. On the basis of estimates such as these it was decided that a LISA experiment could indeed be built for ~350 to 400 kg. Table 2 includes a total of ten options that were considered, along with the Atlas version.

2) Application of new VLSI Circuitry to Astromag: One development that can facilitate a smaller version of Astromag is the use of new, low-power electronics. One objective of this study was to determine whether the custom VLSI circuitry developed by the SRL group for use on the Advanced Composition Explorer (ACE) Mission could be used in the Astromag Cherenkov counter. In particular ACE is developing a single CMOS VLSI circuit that contains 16 complete

pulse-height nalysis chains, each including a preamp, dual level discriminator, sample and hold, 12-bit Wilkinson ADC and test pulser (see Cook et al. 1993). It operates on only 15 mW per chain for a total of 240 mW of regulated power.

Although the ACE circuitry was not available in time to test it directly with the Hamamatsu phototubes (PMTs) base-lined for LISA, the design characteristics of this circuit are compatible with the application in LISA. Assuming that a given PMT would typically see  $\sim$ 3 photoelectrons per relativistic particle with Z=1 and  $\beta$ =1, the 30 pC full scale and dynamic range of >1000 could accomodate relativistic Ni nuclei with Z=28, at the same time as slow Be nuclei (Z=4). The required PMT gain is <10<sup>5</sup>. The maximum conversion time of 256 microseconds is also compatible with the expected event rate. Thus it does appear that these circuits would be very useful in the Cherenkov system at least. The estimated savings would be  $\sim$ 85 mW per ADC.

3) Studies of the Mass Resolution and Yield of a Scaled-down LISA Instrument: Figure 6 shows the orbit-averaged energy spectra for several possible orbits. In its original configuration, LISA was limited to particles greater than ~2 GeV/nucleon by the 28.5 deg orbit of Freedom. As a free flyer, Astromag would no longer be restricted to low latitudes. As a result, the reduced yield implied by a smaller experiment could, to a large extent, be compensated for by the more favorable orbit. Table 3 compares the relative yield of isotopes for the Space Station, Atlas, and Delta versions. Note that with a higher inclination orbit, a smaller Astromag can still obtain sufficient satistical accuracy for high energy isotope studies.

A second advantage of a high-latitude orbit is that allows isotopic studies over a much wider range of energies than did the original Astromag orbit. By choosing aerogel radiators with several indices of refraction from ~1.1 down to ~1.025, the range from ~1 to ~4 GeV/nuc can be covered. Aerogel Cherenkov counters with n=1.043 were successfully tested in a recent balloon experiment (Laborador et al. 1993)

The smaller magnet in the Delta-class version of Astromag will have a somewhat reduced bending power, often characterized as the maximum detectable rigidity (MDR). The Delta version could have an MDR of 1.3 TV, compared to 2.4 TV for the Atlas Version, and 3.2 TV for the Space Station magnet. This will limit somewhat the mass resolution of heavier isotopes at high energy. Figure 7 shows the maximum energy to which isotopes can be resolved if the mass

resolution contribution of the magbetic spectrometer is limited to 0.2 amu. Figures 8 and 9 calculated by Bob Streitmatter, show the expected mass resolution as a function of energy for Si and Fe isotopes. While it will be difficult to resolve adjacent isotopes with Z>20 at energies > 2 GeV/nuc, there are a number of important isotope ratios that are separated by 2 amu, including 54Fe/56Fe, 57Co/59Co, and 60Ni/58Ni, where the required mass resolution is less.

Summary: The results of this study were that the scientific objectives of LISA could indeed be accomplished by a Delta-class version of Astromag.

To: The LISA Astromag Team

From: Dick Mewaldt 71000

Subject: Possible Delta-Class Astromag Designs

I have identified some possible designs for LISA that I estimate will require only about 800 lbs to implement and which may therefore be compatable with launch on a Delta. Although they all require compromises of energy coverage and/or geometry factor, it is possible that they may later be expanded some if we can be more clever in our use of resources, or if additional resources become available. I have made careful evaluations of the requirements of the Cerenkov subsystem for these designs, and have down-sized this system by a factor of 2 to 3 over our Atlas design. I think that the next step is to obtain more accurate estimates for the other subsystems, particularly in the area of structure (see discussion below). We should also see to what extent these designs meet our resolution and yield requirements.

## Summary of Possible Designs

Figures 1 to 4 sketch some possible approaches that represent the gradual steps that I took in reducing the mass. The choice of radiators that go into the modules does not have much effect on the required resources, but in order to achieve the goals of ~750-800 lbs I have had to severely limit the number of Cerenkov modules. This leaves several choices: getting away from redundant Cerenkov measurements; omitting the Pilot counters and relying on the TOF scintillators for charge identification, or severely restricting the number of energy ranges. The basic design I am left with allows for all of these possibilities for similar requirements on the TOF and Hodoscope subsystems. Table 1 summarizes my estimates of the mass and power requirements.

Of the designs shown, numbers 5, 6, and 7 (see Figures 2, 3, 4) are each ~800 lbs. When I was at our meeting in College Park I was favoring #5, which was to have 8 different aerogel counters (of 4 indices, A1 to A4 in Figure 1), but would use only the dE/dx-Aerogel,

or the dE/dX-TOF to measure charge, where dE/dx comes from the scintillator. I now think that this approach probably will not give adequate charge resolution, and I am again favoring putting the Pilot Cerenkov back in to measure charge (and do isotopes below 1 GeV/nuc). To do this I am reducing the number of aerogel counters so that there are only two indices (A1 and A2 in Figure 1), each with two counters. (I still think redundant velocity measurements are important). In any case, the requirements for the hodoscope and TOF are about the same. One possibility that should be considered is a Pilot counter that uses total internal rerflection instead of a white box, so that it can be done for less mass and space.

Version #6 does not adapt itself very well to using the Pilot radiators and I am not now considering it. It originally was to have three modules (2 small and 1 big) featuring three separate indices of aerogel.

Version 7 is the one I now favor. It has only a Pilot counter and TOF at the bottom. There are two indices of aerogel which might be tuned to have thresholds at perhaps ~1 and ~2.5 GeV/nuc. We would also get isotopes from the Pilot counters. Although the design is asymmetric, it seems to me to have all the requirements.

Each of versions 1 to 7 fits into a 2.5 m radius. In versions 5, 6, and 7 the hodoscope separation is about 160 cm and the TOF separation is about 235 cm. The width of the hodoscope and TOF active area in these latter three cases is reduced to 42 cm. In this way I think our overall width will be <0.9 m. I was forced to reduce the hodoscope to 5 layers to meet the weight requirements. We might want to reexamine some of these trade-offs once we have better numbers. If more mass becomes available we can consider adding another module (and energy range) on top, or we can add more hodoscope layers, or PMTs, or increase the counter areas, etc.

### Weight and Power Estimates

For each of the seven designs I have evaluated in detail the resources required for the Cerenkov subsystem. I then attempted to scale the mass and power for the other subsystems to see if I was in the ball-park. The assumed scaling relations are documented in the notes to Table 1.

#### Cerenkov Subsystem

The mass and power estimates in Table 1 are based on the following changes from our Atlas design.

- 1) We are now baselining VLSI circuitry for the PHA and discriminator chains. Much of the work required to implement these designs has been financed by the ACE project; we hope to adapt these designs to the analysis of photomultiplier (PMT) signals within our SR&T effort over the next year or two. We expect to achieve a 12-bit ADC chain that will require only ~0.02 W and 0.04 kg (including the weight of the board). With additional work we may also be able to implement the designs required for TOF circuitry in VLSI. The resulting gains will reduce the mass and power required by LISA, and should also lead to savings in other areas such as power supplies and solar panels.
- 2) The weight of mounted aerogels ~50x50 cm2 in area and their frames and potting material has been measured accurately. This design survived a balloon launch and landing.
- 3) We are now base-lining that the frames that mount the aerogel radiators will fabricated from composite materials; leading to a 40% savings over the use of aluminum.

## Suggestions for Possible Improvements in other Subsystems

Structure: The ratio of inactive "structure" to "detector + electronics" in our Atlas design is ~0.6; which seems very conservative to me. I have maintained this ratio in my estimates for these Delta-class designs (see Table 1), but would like to see more mass freed up for the detectors. Perhaps we can achieve some savings in this area through the use of composite materials.

Central Processor and Power Supplies: The estimated mass and power for this seems very high - much more than we can afford, but I have no visibility into where it is going. I think that <10 kg and <10 W should be more than adequate for the central processor. As an example, In the CRIS experiment on ACE we are doing all of the onboard processing required for six planes of a SOFT hodoscope and four silicon stacks (with 14 ADCs and 20 discriminators) for <5 W and <5 kg. CRIS is of comparable complexity to LISA. We have

similar requirements for on-board processing of the SOFT data, and both experiments must minimize the amount of pulseheight data by transmitting pulseheights only that from those modules that are triggered. The event rates are also comparable, with CRIS having the higher event rate because it has no geomagnetic cutoff. This subsystem also has the functions of accumulating rates, formatting (packetizing) the data, and handling commands, housekeeping etc. The DPU on SAMPEX (designed and built by Aerospace Corp.) handles all of these functions for four different instruments for a total of 6 watts and 3 kg. We need to separate out the processing and power supply functions, and look critically at the requirements for each.

The TOF System: Since the requirements of this system depend on the amount of area covered it is difficult to gain much from the detector system except by reducing the size. However, significant savings would seem to be possible in the weight and power requirements for the electronics by going to VLSI designs. I have already included some savings by assuming that the ADC and discriminator circuits from ACE can be adapted to this system. It is likely that other circuits can also be incorporated into VLSI designs.

The SOFT Hodoscope: It appears to me that the only way to get sufficient savings from this subsystem (once the overall area has been reduced) is to reduce the number of planes from 8xy to perhaps 5x and 5y. This needs to be looked at more closely taking into account the MDR that will result. Other combinations such as 6x and 4y should also be considered, and the fiber thickness should be examined. I certainly hope that the light-tite shield and registration system can be eliminated, but have retained the scaled-down mass here just in case. If still required, maybe the thickness of the light shield can be reduced now that it is smaller. Maybe it can be made from a thin plastic. The resouces required for the camera system and other electronics should be re-evaluated based on the work that has recently been done for ACE. The fact that SOFT will fly on ACE should allow us to carry somewhat less contingency for this system, once we know what it actually takes.

Overall, I think we should have the goal of coming in under my scaled estimates (Table 1) so that we can add more science. It would be very helpful if each subsystem developed simple algorithms to allow the scaling of mass and power by area, number of PMTs or cameras, or some related parameters. Then we can more easily examine the tradeoffs.

	Notes:									
	1) Calculated in detail for all options									
	ctive scintillator area required to cover the C modules									
	3) Generally assume two PMTs for each ~20 cm of width									
	4) Scaled by TOF area + 8 kg; based on Wiedenbeck memo of 2/12/91									
	5) Total required active area of fibers									
	6) Scaled from Atlas version using M = 15 + 80(A2/A1); A2, A1 are active fibe	r areas								
	7) Scaled from Atlas; proportional to active fiber area									
	8) Scaled from Atlas; proportional to active fiber area (Can we drop this now?)									
	9) Assumed to be 2/3 of the 45 kg devoted to the Atlas central control unit.									
	For others scale by P = 5 kg + 25 kg*(Items 33-36)/185									
	10) Assumed to be 15 for Atlas; taken to be 7 for Delta versions									
	11) Given somewhere as 45 on Atlas; summed from items #15 +#16 for Delta									
	12) Scaled by taking 25% of the Cerenkov + TOF weights									
	13) Scaled by taking 10% of everything else; including outer trusses									
	14) Sum of all mass above									
	15) Detailed estimates, including the use of VLSI for Delta versions									
<u> </u>	I don't understand the Atlas # of 63 W.; I think it should be ~50									
	16) Crude estimate scaled by TOF area + 6 watts (see 1/4/91 MEW memo);									
	includes some VLSI in Delta versions									
	17) Crude estimate scaled by Hodo area + 17 watts									
	18) I don't understand the Atlas number of 75 W; 10 W should be more than ade									
	unless the central processor is doing much more than I understand.									
	19) Sum of above numbers									
	20) The Atlas report lists 380 W. for LISA; R. Streitmatter gave me the above break									
	for this (items 21-25)
